1.1 Finite Non-negative Real Numbers

HOL-Probability already provides the extended non-negative real numbers (usually called *ennreal*). That type is ideal for measure theory: non-negative integrals and measures may naturally take the value infinity.

The probabilistic state monad in this development only uses finite, discrete probability weights. For that purpose it is useful to have a smaller type of finite non-negative real numbers, implemented as a subtype of *real*. This avoids proof obligations about infinity while keeping non-negativity as a type invariant.

1.9 Probability Distributions

This is a formalization of a datatype for finite probability distributions.

The mathematical presentation uses finitely supported probability maps. This gives a direct specification of distributions and *bind*: a distribution is a partial map whose domain is finite and whose weights sum to one, and *bind* computes the probability of a

result by summing over the finite support of the first computation.

The most direct code equation for `bind` is not executable for arbitrary result and state types, however. The map operation `dom` needs to enumerate the support of a map, and Isabelle’s generated code can only do that for types in the `enum` class. Thus a purely map-based implementation of `bind` would impose an unwanted executability restriction on the types used by the monad.

To avoid this, the theory keeps the map-based definitions as the abstract specification, but provides alternative executable equations in terms of finite sets. The finite-set representation explicitly stores the support and weights, so generated code can iterate over those stored elements without requiring the underlying types to be enumerable. This makes the executable version suitable for arbitrary result and state types.

A previous list-based version has the same basic idea, but converting finite sets to lists in a canonical way requires an ordering on the element type, so that approach introduces a *linorder* constraint. The finite-set implementation used here is therefore more general: it avoids both the *enum* constraint of map-domain enumeration and the *linorder* constraint of canonical list conversion.

The theory also proofs monadic laws for probability distributions and registers the type as a BNF.

1.10 Finite Set Aggregation

1.11 Probability Maps

1.11.1 Summing probability maps

definition *sum-map* :: ($'a \rightarrow \text{nnreal}$) $\Rightarrow$ *nnreal* **where**
sum-map $f \equiv (\sum i \in \text{dom } f. \text{the } (f\ i))$

type-synonym *prob* = *nnreal*

Probability weights are represented by *nnreal*: finite, non-negative real numbers. Keeping non-negativity as a type invariant avoids carrying explicit $0 \leq p$ assumptions through

sums, bind, map, expectation, and normalization proofs.

Plain *real* would admit negative weights, so every constructor and intermediate probability calculation would need extra invariants and proof obligations to rule them out. Strictly positive reals are also not a good fit: the development needs a zero weight for absent probabilities, empty sums, pruning zero-mass outcomes, and intermediate aggregation before the stored support is normalized.

The separate invariant on the distribution type below that excludes zero weights from the domain is therefore intentional. The weight type supports zero where computations need it, while distributions store only the non-zero support.

abbreviation *some-map*

1.19 Hashing

Protocols should not encode semantically different random-oracle queries as the same raw value before hashing. The STARK protocol uses field-valued hash outputs and messages, but Merkle leaves, Merkle internal nodes, and Fiat-Shamir challenge queries need distinct input domains. The datatype below provides that shared domain-separated input vocabulary.

```
datatype 'a protocol-hash-input =
  MerkleLeaf 'a
| MerkleNode 'a 'a
| FiatShamirChallenge 'a
| TraceFriChallenge nat 'a
| CompositionFriChallenge nat 'a
| AlphaChallenge nat 'a
| QueryIndexChallenge nat 'a
```

```
record ('a, 'b) hash =

begin
```

1.23 Boolean Interpretation

```
global-interpretation test-channel:
```

```
  channel concat-bool
```

```
  defines test-send = test-channel.send
```

```
    and test-send2 = test-channel.send2
```

```
    and test-read = test-channel.read
```

```
  .
```

```
value execute (receive-random-field-element) ( $\lambda$ HashMap = (fmempty::(bool, bool) fmap), State = True, Transcript=[])
```

```
value execute (test-send True) ( $\lambda$ HashMap = (fmempty::(bool, bool) fmap), State = True, Transcript=[])
```

The idea is that if we process a transcript then we recover the state and get the same random element. To this end we need to execute the monad on the final HashMap, the initial state and the reversed transcript. Each read then modifies the state in the same way as a send which leads to the same result for the hash value used to create the random value.

```
value
```

```

1.26 Merkle Trees

This theory defines Merkle tree creation, authentication paths, and checking in the probabilistic hash monad. The STARK prover uses these commitments for trace, composition, and FRI layers, while the verifier checks sampled openings against the recorded roots.

```

fun get-authentication-path::nat ⇒ nat ⇒ 'a tree ⇒ 'a list
where
  get-authentication-path lgth idx (Node l v r) =
    (if lgth = 1 then [] else
      (if idx < lgth div 2
        then (value r) # (get-authentication-path (lgth div 2) idx l)
        else (value l) # (get-authentication-path (lgth div 2) (idx - (lgth div 2)) r)))

1.30 Domain-separated protocol Merkle interface

The generic Merkle locale already separates hash outputs from hash inputs: leaves have a separate input type, hash outputs have the field type, and internal nodes are encoded by the locale parameter. Instantiating that parameter with the constructor `MerkleNode` and wrapping leaves with `MerkleLeaf` gives the STARK protocol a domain-separated Merkle API without duplicating the existing Merkle proofs.

global-interpretation *protocol-merkle:*

merkle-tree ($\lambda x y. \text{MerkleNode } x y$)

```

defines protocol-merkle-create-raw = protocol-merkle.create
and protocol-merkle-check-authentication-path-raw =

    protocol-merkle.check-authentication-path len idx (MerkleLeaf leaf) path

```

1.31 Sanity Check

```

context merkle-tree
begin

```

The created-tree predicate is a proof-only invariant connecting the result of create to the final hash-map state. It is needed because create samples hashes probabilistically, while authentication-path checking later recomputes hashes. To prove the recomputation succeeds with probability 1, the proof needs to know those sampled hashes are already recorded in the hash map, so future calls to hash replay the same values instead of sampling fresh ones. So the created-tree predicate is not part of the Merkle API. It is a ghost invariant used to bridge "this tree was produced by create" and "checking its authentication path will replay the same root hash."

```

fun created-tree::'b list  $\Rightarrow$  'a tree  $\Rightarrow$  ('b, 'a, 'c) hash-scheme  $\Rightarrow$  bool
where
  created-tree [] t s  $\longleftrightarrow$  t =  $\langle \rangle$

1.36 Stark Protocol

This theory defines the executable prover and verifier monads for the STARK protocol formalized in this entry. It also fixes the common domain parameters, transcript operations, Merkle commitments, query sampler, and FRI folding routines used by the completeness and soundness developments.

The formalization follows the structure of the StarkWare STARK tutorial and the algebraic framework described in the STARK literature. The field class uses Proth fields because their multiplicative groups provide the power-of-two subgroups used for FFT-style evaluation domains.

1.37 Preliminaries

definition *ceil-log* :: *nat* ⇒ *nat* **where**
ceil-log *n* = (if *n* ≤ 1 then 0 else Suc (floor-log (*n* - 1)))

1.37.1 Filter list by predicate over length

There exists *nths* in List which does what we want but it cannot be executed. Thus, we introduce a new function with a corresponding code equation which makes it executable.

definition *nths-pred*
where
nths-pred *xs* *P* ≡ *nths* *xs* (Collect *P*)

lemma *nths-pred-nths*[code]:
nths-pred *xs* *P* = map fst (filter (λ*p*. *P* (snd *p*)) (zip *xs* ([0..*length xs*])))
unfolding *nths-pred-def* *nths-def* **by** *simp*

lemma *nths-pred-alt-def*[*simp*]:

nths-pred *xs P* = *nths xs (Collect P)*
unfolding *nths-pred-def* ..

lemma *nths-pred* ([5,6,3,4]::nat list) even = [5,3] **by** *eval*
lemma *nths-pred* ([5,6,3]::nat list) even = [5,3] **by** *eval*
lemma *nths-pred* ([5,6,3]::nat list) odd = [6] **by** *eval*
lemma *nths-pred* ([6,3]::nat list) even = [6] **by** *eval*
lemma *nths-pred* ([6,3]::nat list) odd = [3] **by** *eval*

lemma *nths-pred-length-leq*:
length (nths-pred xs P) ≤ length xs
unfolding *nths-pred-def nths-def*
by (*metis length-filter-le length-map map-fst-zip map-nth*)

Many properties can be more easily proven if we use *zip xs (rev [0..<length xs])*. Thus, we introduce the following lemmas which can be used to convert the lemmas back to *nths-pred*.

lemma *filter-zip-lcomp*:
assumes *xs ≠ []*
shows
filter (λp. P (snd p)) (zip xs [0..<length xs]) = [(xs!i,i). i ← filter P [0..<length xs]]

protocol-channel-compat +

constrains $\omega::'f::proth-field$

and $shift::'f$

and $g::'f$

and $h::'f$

and $vals::'f\ list$

and $concat :: 'f \Rightarrow 'f \Rightarrow 'f$

fixes $\omega::'f::proth-field$ — This is assumed to be a generator of $'f$

and $shift::'f$ — This shifts H to the evaluation-domain coset.

and $scale::nat$ — This is the scaling or blow-up factor

and $clength::nat$

— The length of the computation, it does need to be a power of two or else needs to be padded to the next power of 2

and $powers::nat$

— The number of powers of the generator required for the spec $[0..<powers]$. This is basically the size of the list which is passed to the first element of *spec*

and $to-nat::'f \Rightarrow nat$

and $of-nat::nat \Rightarrow 'f$

— Functions to transfer from $'f$ to the field and back

and $size::nat$

— The size of $'f$

and $spec:: (('f\ poly\ list \Rightarrow 'f\ poly) \times nat\ list \times nat)\ list$

— The specification consists of a list of three elements: A constraint polynomial, i.e., a function which creates a polynomial from a list of polynomials (the input here is assumed to be the trace polynomial scaled by powers of the generator); A list of roots for a given constraint polynomial; The degree of the constraint polynomial (actually this could be computed but for now we give it explicitly)

and $rounds::nat$

assumes *size-card*: $size = CARD('f)$ — This is just there since $CARD$ cannot be computed

and *clength-pow*: $\exists k. clength = 2^k$

— We assume the trace has correct length. In reality this is not required since we can just add padding.

and *scale-pow*: $\exists k. scale = 2^k$ — This needs to be a power of two to make definition of h well-defined

and *omega-order*: *exact-order omega* ($size - 1$)

— *omega* is a primitive generator of the multiplicative group.

and *eval-domain-dvd*: $clength * scale \text{ dvd } size - 1$

and *eval-domain-nontrivial*: $1 < clength * scale$

and *of-nat-to-nat*: $\forall x. \text{of-nat } (\text{to-nat } x) = x$

and *to-nat-range*:

$range \text{ to-nat} = \{0..<size\}$

— Exact-uniformity assumption for the current query sampler, which samples a field element and maps it through *to-nat* and modulo reduction. A direct sampler over the query sample space, or a rejection sampler with a proved distribution, would remove this divisibility condition from the protocol locale.

and *powers-le-clength*: $powers \leq clength$

and *powers-pos*: $0 < powers$

and *query-sample-space-size-dvd*:

$clength * scale - Max (set [0..<powers]) * scale \text{ dvd } size$

— Exact-uniformity assumption for modulo reduction into the current query sample space.

It is specific to the current field-element encoding based sampler.

and *shift-nonzero*: $shift \neq 0$

and *two-nonzero*: $(2::'f) \neq 0$

and *spec-degree-fits*:

$\bigwedge c \text{ roots } d.$

$(c, roots, d) \in set \text{ spec} \implies$

$d * (clength - 1) - length \text{ roots} < clength * scale$

and *constraint-degree-wellformed-raw*:

$\bigwedge f c \text{ roots } d.$

$degree \text{ f} < clength \implies$

$(c, roots, d) \in set \text{ spec} \implies$

$degree$

$(c \text{ (map}$

$(\lambda p. f \circ_p XP ((\omega \wedge ((size - 1) \text{ div } clength)) \wedge p))$

$[0..<powers]))$

$\leq d * (clength - 1)$

and *spec-roots-in-range*:

$\bigwedge c \text{ roots } d \text{ r.}$

$(c, roots, d) \in set \text{ spec} \implies$

$r \in set \text{ roots} \implies$

$r < clength$

and *spec-roots-distinct*:

$\bigwedge c \text{ roots } d.$

$(c, roots, d) \in set \text{ spec} \implies$

$distinct \text{ roots}$

and *shift-notin-H-raw*:

$shift \notin$

1.38.2 Basic definitions

G is a subgroup of $'f^x$ (the multiplicative group of $'f$). It is generated by generator g and contains exactly as many elements as the length of the (padded) execution trace.

definition g

where

$g \equiv \text{omega}^{((\text{size} - 1) \text{ div } \text{clength})}$

definition *trace-powers-of* :: $'f \text{ poly} \Rightarrow 'f \text{ poly list}$

where *trace-powers-of* $f = \text{map } (\lambda p. f \circ_p XP (g \wedge p)) [0..<\text{powers}]$

lemma *trace-powers-of-length*[*simp*]:

$\text{length } (\text{trace-powers-of } f) = \text{powers}$

unfolding *trace-powers-of-def* **by** *simp*

lemma *constraint-degree-wellformed*:

— This locale fact records a syntactic degree side condition for *spec*. A stronger syntactic degree-analysis interface could derive it in a later refinement of the specification layer.

assumes $\text{degree } f < \text{clength}$
and $(c, \text{roots}, d) \in \text{set spec}$
shows $\text{degree } (c (\text{trace-powers-of } f)) \leq d * (\text{clength} - 1)$
using $\text{constraint-degree-wellformed-raw}[OF \text{ assms}]$
unfolding $\text{trace-powers-of-def } g\text{-def}$.

definition G

where

$G = \text{map } ((\frown) g) [0..<\text{clength}]$

H is again subgroup of f^x . Its size is the size of G scaled by the scaling factor scale . It is generated by generator h .

definition h

where

$h \equiv \text{omega}^\wedge((\text{size} - 1) \text{ div } (\text{clength} * \text{scale}))$

definition H

where

$H = \text{map } ((\frown) h) [0..<\text{scale} * \text{clength}]$ — Since both scale and clength are powers of two their product is a power of two as well

lemma $\text{shift-notin-}H$:

$\text{shift} \notin \text{set } H$

using $\text{shift-notin-}H\text{-raw}$

unfolding $H\text{-def } h\text{-def}$.

We generate a Coset(<https://en.wikipedia.org/wiki/Coset>) of H for our evaluation domain by multiplying each element with a nonzero shift.

definition eval-domain

where

$\text{eval-domain} = \text{map } ((* \text{shift}) H$

This function creates the indices which need to be evaluated for the de-commitment phase. Note that the verifier needs to obtain values of f for all the powers in powers to compute the constraint polynomial. Also, in the flat representation a power actually means that the index is multiplied by the scale factor.

definition powers-scaled

where

$\text{powers-scaled } \text{idx} \equiv \text{map } (\lambda x. \text{idx} + (x * \text{scale})) [0 ..< \text{powers}]$

definition index

where

$\text{index } x = x \text{ mod } ((\text{clength} * \text{scale}) - ((\text{Max } (\text{set } [0 ..< \text{powers}])) * \text{scale}))$

definition $g\text{-map}$

where

$g\text{-map } rs = (\text{map } ((\frown) g) rs)$

```

1.38.3 Composition polynomial

The composition polynomial is a random linear combination of the constraint polynomials divided by their roots. Note that in reality we don't compute the product polynomial as here. Instead we use a trick to optimize the computation (described here under Succinctness: <https://medium.com/starkware/arithmeticization-ii-403c3b3f4355>) Also note that it needs to be parametrized by *f* since the prover uses it with the real *f* whereas the verifier uses another *f*. Maybe we need different versions for prover and verifier later on.

```

definition cp
where
   $cp \text{ as } fs \equiv \text{fold } (\lambda(a, (p, rs, -)). (+) ((CP \ a) * ((p \ fs) \text{ div } (\text{prod } (g\text{-map } rs)))))) (\text{zip as spec}) \ 0$ 
end

```

1.39 Prover

Only the prover knows the actual execution trace.

```

locale prover = stark +
  constrains omega::'f::proth-field
    and shift::'f
    and concat :: 'f  $\Rightarrow$  'f  $\Rightarrow$  'f
    and spec :: (('f poly list  $\Rightarrow$  'f poly)  $\times$  nat list  $\times$  nat) list

```

fixes *vals::'f list* — This is the actual computation trace

assumes *trace-length: clength = length vals*

begin

1.39.1 Trace Polynomial

The interpolated polynomial from the trace over G . We do it using Lagrange interpolation. In practice it is usually done using IFFT (inverse FFT – Fast Fourier) but could not find it in the AFP.

definition *f*

where

f $\equiv$ *lagrange-interpolation-poly* (*zip G vals*)

Now we evaluate the trace polynomial on the larger domain, creating a Reed-Solomon error correction code.

definition *f-eval*

where

f-eval $\equiv$ *map* (*poly f*) *eval-domain*

Similar as the trace polynomial we evaluate the composition polynomial on the larger domain.

definition *f-powers*

where

f-powers $\equiv$ *map* ($\lambda p. f \circ_p XP (g \hat{p})$) [*0* ..< *powers*]

definition *cp-eval*

where

cp-eval as $\equiv$ *map* (*poly* (*cp as f-powers*)) *eval-domain*

3 Executable Example

```

theory Square-Sequence
  imports
    Stark-Core.Stark
    HOL-Number-Theory.Number-Theory
    Stark-Core.Galois-Field-5
begin

```

3.1 Square Sequence Example

In the following example we generate a proof for a program which computes the square sequence: $x, x^2, x^4, \dots$ Since the computation is probabilistic we keep the executable example small: a sequence of size 2 with scaling factor 1.

We use $\text{GF}(5)$ - the finite field of order 5 - for our example.

- It is a Proth field.
- It is large enough for a trace of length 2 with a scaling factor of 1 and a shifted evaluation domain disjoint from H .
- It is still feasible to execute probabilistically. Larger fields make the executable example substantially more expensive.

3.2 Polynomial Constraints

The first number in the sequence (at position 0) is 2

definition $p0:: gf5\ poly\ list \Rightarrow gf5\ poly$

where

$$p0\ f \equiv f!0 - 2$$

definition $r0:: nat\ list$

where

$$r0 \equiv [0]$$

The last number in the sequence (at position 1) is 4

definition $p1:: gf5\ poly\ list \Rightarrow gf5\ poly$

where

$$p1\ f \equiv f!0 - 4$$

definition $r1:: nat\ list$

where

$$r1 \equiv [1]$$

For all intermediate positions (which is only position 0) the next position is the square of the previous position.

definition $p2:: gf5\ poly\ list \Rightarrow gf5\ poly$

where

$$p2\ ps \equiv ps\ !\ 1 - (ps\ !\ 0 * ps\ !\ 0)$$

definition $r2:: nat\ list$

where

$$r2 \equiv [0..<1]$$

The spec consists of a list containing the above constraints. Note that the third parameter in each entry is the degree of the constraint polynomial.

definition $spec::((gf5\ poly\ list \Rightarrow gf5\ poly) \times nat\ list \times nat)\ list$

where

$$spec = [(p0, r0, 1), (p1, r1, 1), (p2, r2, 2)]$$

We also need the spec in an other format. These need to be equivalent and for the future it should be unified with the other spec.

definition $p0':: gf5\ list \Rightarrow gf5$

where

$p0' f \equiv f!0 - 2$

definition $p1':: gf5\ list \Rightarrow gf5$

where

$p1' f \equiv f!0 - 4$

definition $p2':: gf5\ list \Rightarrow gf5$

where

$p2' ps \equiv ps ! 1 - (ps ! 0 * ps ! 0)$

definition $spec2::(gf5\ list \Rightarrow gf5) \times nat\ list \Rightarrow list$

where

$spec2 = [(p0', r0), (p1', r1), (p2', r2)]$

unfolding query-future-fresh-def by simp

```

The current bound has no separate Merkle-binding error term. Merkle binding is represented by the conditional premise *initial-merkle-binding-no-bad* below, because the present hash-map model does not assign a collision-resistance probability to Merkle roots.

4.1 Proof structure for soundness

The proof should decompose an accepting verifier execution for a false statement into four bad events:

- the trace FRI accepts a table that is not the evaluation of a trace polynomial satisfying *degree f < clength*;
- the composition FRI accepts a table that is not low-degree;
- the random linear combination hides a violated constraint;
- the verifier's sampled query indices miss all disagreement points.

The following predicates and lemmas are the intended interface between the probabilistic proof over *verify-monad* and the deterministic algebraic arguments.

```

definition accepted :: ('x × 's) option ⇒ bool
where accepted out ⇔ ¬ Option.is-none out

```

```

definition trace-table-low-degree :: 'f list ⇒ bool
where
  trace-table-low-degree ys ⇔
    (∃ f. degree f < clength ∧ ys = map (poly f) eval-domain)

A successful verifier execution only checks the sampled authentication paths. Turning those local checks into full trace and composition tables bound to the initial committed roots is a Merkle binding/collision-resistance property. The current random-oracle hash-map model records enough information to replay checked paths, but it does not by itself imply existence or uniqueness of a complete maliciously committed table. We therefore expose the missing part as a bad event over accepted verifier executions. Binding for intermediate FRI layers is not hidden here; it is part of the FRI bad-challenge-set reductions introduced below.

 $\text{composition-error-bound})$

The protocol currently represents all Fiat-Shamir challenges through the same random-oracle hash map, without protocol-level domain-separated labels for alpha, query-index, and FRI challenges. The following predicates below state the precise freshness obligations needed for each challenge family. Phase 4E bundles them into one random-oracle model interface rather than adding labels to the protocol in this refactor. Merkle hash uses are not represented as freshness obligations here; their binding role remains the explicit *initial-merkle-binding-no-bad* premise.

At this stage *accepted-with-tables* is the boundary between the verifier execution and the algebraic proof. It records the trace table, composition table, and verifier challenges associated with an accepted execution. It now also records that the initial verifier transcript has the expected header shape and that the sampled query positions are locally consistent with the associated tables. Merkle binding is separated into *accepted-with-bound-tables*, because malicious binding requires additional Merkle/collision-resistance reasoning.
