The multiround bad-set constructors above isolate the proof-only part of the FRI reduc-

tions: once an algebraic cover and the corresponding error-fraction bound are available, the existing opening-reduction assumptions follow directly. The current transcript predicate records authenticated local openings, but it does not bind complete intermediate FRI layer tables. Thus the algebraic cover is still an external FRI/table-binding theorem target unless the protocol model is extended with such tables or an equivalent binding interface.

The remaining soundness interfaces have the following status without changing the protocol. The predicate *initial-merkle-binding-no-bad* is a cryptographic/model boundary excluding accepted executions whose local Merkle openings cannot be extended to full committed tables. The predicate *random-oracle-freshness-assumption* is a random-oracle model boundary: its component projections are deterministic, but deriving freshness itself would require assumptions about the hash oracle, and deriving domain separation internally would require protocol labels that are not present in the current formalization. The two FRI reduction interfaces are proof obligations rather than protocol changes. Each packages an opening-transcript algebraic cover with a bounded bad-challenge-set statement. The lemmas below derive the verifier bad-event bounds directly from those opening-based interfaces.

lemma *trace-fri-bad-bound-from-opening-reduction*:

begin

The deterministic partition above reduces soundness to four probability bounds. The bounds themselves require additional cryptographic/algebraic interfaces: random-linear-combination soundness, query-sampling freshness, and FRI low-degree soundness. Those assumptions are kept in the separate bounded-soundness locale below, rather than hidden as unproved lemmas in this base locale.

lemma *soundness-bound-component-accounting*:

soundness-bound =

imports
  Soundness-Staged-Query-Prefix
  Soundness-Bound-Table-Partial-Openings
begin

```

Partial-opening query events for staged soundness.

This layer records query consistency directly from authenticated openings. It deliberately avoids the stronger, generally false claim that sampled openings determine unique complete trace and composition tables.

theory Staged-Security-Experiment-Composition-Partial
  imports
    Staged-Security-Experiment-Composition-Branch
    Soundness-Reductions-Composition
begin

Partial-candidate composition reductions for the staged security experiment.
This layer avoids treating verifier-side Merkle subtree recomputation as a rare event.
Instead, it lifts the verifier-local reduction from composition alpha badness to a partial-
header candidate event plus hash collision.

qed

Vector-valued, prefix-state-dependent accounting for future alpha challenge keys. The bad vector set may be selected from the concrete verifier/header state reached after the alpha prefix; the bound is derived from the existing relation-budget interface for the prefix program, not from a freshness assumption.

theory *Soundness-Staged-Candidate-Query*

imports

Soundness-Staged-Query

Soundness-Staged-Partial-Query

begin

Candidate-indexed dynamic query-prefix targets.

These targets are narrower than the old global partial-opening fixed cover: they are parameterized by one fixed trace/composition candidate pair and the authenticated openings extracted for that pair. This is the shape needed for the composition candidate-drift query case, where the target must be chosen before the query-index challenge is sampled.

context *soundness*

theory Staged-Security-Experiment-Composition-Query-Residual
imports
  Staged-Security-Experiment-Composition-Partial
  Soundness-Staged-Partial-Query-Branch
  Soundness-Staged-Candidate-Query
begin

```

Composition-specific residual split after the alpha-prequery accounting.

The broad branch-subtree witness event is not rare: honest verifier-side Merkle path re-computation can produce such witnesses. This layer therefore splits the actual remaining composition drift event itself into a part covered by the sampled partial-opening query event and a residual part that is still to be discharged by the Merkle/candidate proof.

context *soundness*
begin

The existing committed query-prefix targets are based on *query-sampling-success-space*. They are suitable for ordinary query inconsistency, but not directly for composition randomization witnesses: *composition-bad-context* already requires all sampled queries to be consistent. Hence the query-sampling success space of the actual composition witness is empty, and the composition-drift query case needs a narrower candidate-indexed target rather than the global partial-opening fixed cover.

theory Soundness-Partial-Initial-Aligned
imports Soundness-Query-Opening-Consistency
begin

```

Aligned partial initial-opening evidence.

The predicate *accepted-with-partial-initial-openings* records trace and composition openings with separate query-index lists. For query soundness bounds this theory packages the stronger verifier-local fact that both opening families come from the same query-round execution and therefore use the same sampled query indices.

theory *Soundness-Aligned-Partial-Query*
imports *Soundness-Partial-Initial-Aligned*
begin

Aligned partial-candidate query events.

This layer records the query-bad shape needed by the staged prefix-target proof: one shared verifier query-index list for trace and composition openings, together with the local composition equation checked in each query round. It is downstream of the staged query-opening extraction layer to avoid import cycles with the core deterministic reductions.

theory Soundness-Aligned-Partial-Query-Transcript
imports
  Soundness-Aligned-Partial-Query
  Soundness-Staged-Partial-Query
begin

```

Transcript-tied aligned partial-query events.

The aligned partial-opening predicate records that trace and composition openings use the same sampled query indices. For probabilistic query bounds we additionally need those indices to be the verifier-derived Fiat-Shamir query indices. This layer adds that transcript replay fact without changing the protocol model.

  Soundness-Staged-Transcript
begin

```

Bridge aligned partial-query evidence to prefix-local staged query targets.

The lemmas here are deterministic: they say that, once a verifier query index is replayed to a prefix receive and the prefix alphas agree with the accepted transcript, the aligned partial-candidate query evidence produces a hit in the existing prefix-local target. Probability bounds remain in the staged prefix-target layer.

```

Augmented query-prefix events for the composition query side.

These events live in the query-prefix augmented experiment, so the sampled query challenge is part of the event output. This is the correct setting for applying fixed-witness query-prefix bounds. The fixed-witness event below deliberately does not existentially choose openings after the query challenge; the remaining public-proof work is to derive such fixed witnesses from pre-query Merkle/candidate evidence or charge failures to existing side events.

qed

The next wrapper lets downstream composition proofs conjoin their own side-condition with the fixed authenticated-opening query-prefix hit, without changing the probability bound. This is deliberately fixed-witness: the trace and composition openings are chosen before the query challenge is sampled.

theory Staged-Security-Experiment-Composition-Query-Prefix-Witness
  imports Staged-Security-Experiment-Composition-Query-Augmented
begin

```

Witness-level bridge for the composition query-prefix path.

The existing query-prefix bounds are fixed-witness bounds: the trace and composition openings must already be selected before the query challenge is sampled. This layer records the exact local bridge from such fixed witness data to the augmented query-prefix component event. The remaining public soundness work is to derive these fixed witnesses from prefix Merkle/candidate evidence, or charge failures to existing Merkle/collision side events.

theory Soundness-Partial-Merkle-Cross
  imports Soundness-Partial-Merkle
begin

```

Cross-state Merkle facts for partial authenticated openings.

The broad query-header candidate relation can be supported by different verifier executions and therefore different final hash-map states. These lemmas isolate the reusable binding fact available in the current model: two authenticated openings for the same root, length, and index cannot carry different values across compatible cleanly-merged states.

imports

Soundness-Reductions-Composition

Soundness-Partial-Merkle-Cross

begin

Witnessed query-header partial candidates.

The public query-header candidate set hides the authenticated opening witnesses behind existentials. This layer exposes those witnesses so that the cross-state partial-Merkle binding lemmas can be applied before reducing back to the old candidate-set interface.

imports
Staged-Security-Experiment-Composition-Query-Prefix-Witness
Soundness-Query-Header-Cross-Candidate
begin

Per-round decomposition for the header-authenticated composition query event.

The global event existentially ranges over the query round and authenticated opening witnesses. This layer peels off the finite round existential. The remaining witness selection problem is deliberately left explicit: later proofs must either choose prefix-fixed witnesses before the query challenge or charge failures to Merkle/collision side events.

theory *Staged-Security-Experiment-Composition-Query-Current*
imports *Staged-Security-Experiment-Composition-Query-Classification*
begin

Current-execution projection for the composition query branch.

The broader header-supported query witnesses are existential over possible verifier executions. This layer only reasons about openings authenticated in the actual sampled verifier final state, so the sampled query lookup is available and the event projects to the existing data-state partial-opening query event.

begin

```

Candidate-binding gap for the query-prefix composition route.

The dynamic header-supported query target is small only for candidates that are already visible in the prefix oracle state. This layer isolates the remaining proof obligation: if a later authenticated candidate pair is not in that prefix candidate set, the gap must be charged to Merkle/collision side events in the next proof layer.

(*Some* (((*prefix*, *prefix-state*), *raw*), *raw-state*))))

The preceding actual-alpha event is a diagnostic compatibility predicate: it existentially ranges over query-prefix branches. It should not be bounded directly from query-prefix target budgets unless a separate projection lemma is proved. Bounded public-route arguments should keep the event at the query-prefix data-state layer, or use an explicitly aligned actual-alpha predicate whose query-prefix output is fixed by the run.

theory Staged-Security-Experiment-Composition-Query-Single-Round
  imports Staged-Security-Experiment-Composition-Query-Binding-Gap
begin

```

Same-run single-round candidate binding for the composition query branch.

The actual-alpha diagnostic events in the previous layer intentionally record enough data to relate a candidate pair to a query-prefix target, but they are too broad for Merkle path-output accounting because the query-prefix branch is existential. This layer states the single-round binding gap directly over the query-prefix data-state experiment, where prefix state, sampled query, verifier continuation, and authenticated openings are from the same run.

begin

```

Diagnostic lemmas for the alpha-header partial-candidate route.

The staged composition proof uses *alpha-header-supported-partial-trace-table-candidates*. This candidate set is trace-only, but it has the same sparse-opening obstruction as the query-header partial-candidate set: sampled authenticated openings do not determine unopened trace-table positions.

imports

Soundness-Alpha-Header-Candidate-Blocker

Soundness-Partial-Merkle-Cross

begin

Witnessed alpha-header partial trace candidates.

This layer keeps verifier outcomes and authenticated opening witnesses explicit. It proves the trace-only analogue of the query-header cross-candidate decomposition: if witnessed candidates are not singleton, then either pairwise opening coverage fails or a Merkle/collision side condition occurs.

context *soundness*
