A semantic adversary is an arbitrary probabilistic state-monad program that returns a complete proof transcript. Admissibility states the random-oracle laws needed by the security proof: oracle consistency, bounded range growth, bounded collisions, and bounded hits on every fixed target set.

This interface deliberately does not prescribe an attacker programming language. A future capability-safe command language may expose only probabilistic computation and random-oracle queries, with a refinement theorem showing that every query-bounded

command program satisfies *admissible-adversary*.

 imports *Staged-Security-Experiment-Composition*
begin

Bridges for the composition tree-output side event.

The actual-alpha-prefix experiment carries the concrete alpha-prefix state through the verifier run. This layer relates that path-specific event back to the ordinary checked data-state experiment, so later bounds can be proved once for the data-state event.

```

Branch-specific tree-output events.

The actual-prefix tree-output events are existential over verifier witnesses for a fixed prefix. They are useful for deterministic reductions, but too coarse for direct verifier-local WP bounds. The following auxiliary events tie the witness to the current verifier branch of the checked experiment, so target-budget lemmas can be applied without changing the public theorem interface.

theory *Staged-Security-Experiment-Composition-Bounds*
 imports *Staged-Security-Experiment-Composition-Tree-Output*
begin

Budget-level composition corollaries for the staged security experiment.

This layer consumes the actual-alpha-prefix prequery accounting theorem and exposes the remaining composition side condition as the tree-output event only. The tree-output event is still Merkle/candidate proof work; the alpha-key prequery accounting itself is derived from the current staged oracle-budget interface.

4.4 Partial Merkle Openings

This theory records the authenticated openings that the verifier actually observes. It provides partial table candidates, consistency predicates, and reductions from inconsistent authenticated openings to hash-collision events.

```

record 'f authenticated-opening =
  opening-root :: 'f

```

```

opening-length :: nat
opening-index  :: nat
opening-value  :: 'f
opening-path   :: 'f list

fun merkle-path-bound
  :: 'f ⇒ nat ⇒ nat ⇒ 'f ⇒ 'f list ⇒
    ('f, 'a) protocol-channel-scheme ⇒ bool
where
  merkle-path-bound rt len idx v [] s ⟷
    fmlookup (HashMap s) (MerkleLeaf v) = Some rt
| merkle-path-bound rt len idx v (sibling # path) s ⟷
    (if idx < len div 2 then
      (∃ child.
        merkle-path-bound child (len div 2) idx v path s ∧
        fmlookup (HashMap s) (MerkleNode child sibling) = Some rt)
    else
      (∃ child.
        merkle-path-bound child (len div 2) (idx - len div 2)
